Abstract

Background: The COVID-19 pandemic has caused morbidity and mortality, as well as, widespread disruption to people's lives and livelihoods around the world. Given the health and economic threats posed by the pandemic to the global community, there are concerns that rates of suicide and suicidal behaviour may rise during and in its aftermath. Our living systematic review (LSR) focuses on suicide prevention in relation to COVID-19, with this iteration synthesising relevant evidence up to June 7th 2020.

Method: Automated daily searches feed into a web-based database with screening and data extraction functionalities. Eligibility criteria include incidence/prevalence of suicidal behaviour, exposure-outcome relationships and effects of interventions in relation to the COVID-19 pandemic. Outcomes of interest are suicide, self-harm or attempted suicide and suicidal thoughts. No restrictions are placed on language
or study type, except for single-person case reports.

**Results:** Searches identified 2070 articles, 29 (28 studies) met our inclusion criteria, of which 14 articles were research letters or pre-prints awaiting peer review. All articles reported observational data: 12 cross-sectional; eight case series; five modelling; and three service utilisation studies. No studies reported on changes in rates of suicidal behaviour. Case series were largely drawn from news reporting in low/middle income countries and factors associated with suicide included fear of infection, social isolation and economic concerns.

**Conclusions:** A marked improvement in the quality of design, methods, and reporting in future studies is needed. There is thus far no clear evidence of an increase in suicide, self-harm, suicidal behaviour, or suicidal thoughts associated with the pandemic. However, suicide data are challenging to collect in real time and economic effects are evolving. Our LSR will provide a regular synthesis of the most up-to-date research evidence to guide public health and clinical policy to mitigate the impact of COVID-19 on suicide.

Introduction
The COVID-19 pandemic is causing widespread societal disruption and loss of life globally. By the end of June 2020 over 10 million people had been infected and over 500,000 had died (Worldometer, 2020). There are concerns about the impact of the pandemic on population mental health (Holmes et al., 2020). These stem from the impact of the virus itself on people infected, as well as front-line workers caring for them (Kisely et al., 2020), and on population mental health from the public health measures that have been implemented to minimise the spread of the virus – in particular physical distancing, leading to social isolation, disruption of businesses, services and education and threats to peoples’ livelihoods. Physical distancing measures have resulted in substantial rises in unemployment, falls in GDP and concerns that many nations will enter a prolonged period of deep economic recession.

There are concerns that suicide and self-harm rates may rise during and in the aftermath of the pandemic (Gunnell et al., 2020; Reger et al., 2020). Time-series modelling indicated that the 1918-20 Spanish Flu pandemic, which caused well over 20 million deaths worldwide, led to a modest rise in the national suicide rate in the USA (Johnson & Mueller, 2002; Wasserman, 1992). Likewise, there is evidence that suicide rates increased briefly amongst people aged over 65 years in Hong Kong during the 2003 SARS epidemic, predominantly amongst those with more severe physical illness and physical dependency (Cheung et al., 2008).

The current context is, however, very different from previous epidemics and pandemics. The 2003 SARS epidemic was restricted to relatively few countries. Furthermore, during the 100-year period since the 1918-20 influenza pandemic, global and national health systems have improved, international travel and the speed of communication of information (and disinformation) have increased, antibiotics are available to treat secondary infection, and national economies have become more inter-dependent. The availability of the internet and technological advancement has made it far easier for people to communicate and engage in home working and home schooling. However, there are marked social inequalities in relation to access to technology and ability to stay safe and continue to work, within and between countries. Public health policies and responses, and the degree of access to technology to facilitate online clinical assessments and treatments differ greatly between countries.

Key concerns in relation to suicide prevention during the pandemic include: uncertainty regarding how best to assess and support people with suicidal thoughts and behaviours, whilst maintaining physical distancing; people who have attempted suicide may not attend hospitals because they are worried about contracting COVID-19 or being a burden on the healthcare system at this time; diminished access to community-based support; exposure to traumatic experiences; and an economic recession may have an adverse impact on suicide rates (Chang et al., 2013; Stuckler et al., 2009). There have been increases in bereavement (with many being unusually complicated during the crisis), sales of alcohol (Finlay & Gilmore, 2020) and domestic violence (Mahase, 2020) – all risk factors for suicide (Turecki et al., 2019); the insensitive or irresponsible media reporting of suicide deaths associated with COVID-19 may be harmful; and in some countries access to highly lethal suicide methods such as firearms and pesticides may rise (Gunnell et al., 2020).

In the context of the COVID-19 pandemic there is likely to be a rapidly expanding research evidence base on its impact on suicide rates, and how best to mitigate such effects. It is therefore important that the best available knowledge is made rapidly available to policymakers, public health specialists and clinicians. To facilitate this, we are conducting a living systematic review focusing on suicide prevention in relation to COVID-19. Living systematic reviews are high-quality, up-to-date online summaries of research that are regularly updated, using efficient, often semi-automated, systems of production (Elliott et al., 2014). This paper reports the first set of findings from the review, based on relevant articles identified up to June 7th 2020.

Aim
The overarching aim of the review is to identify and appraise any newly published evidence from around the world that assesses the impact of the COVID-19 pandemic on suicide deaths, suicidal behaviours, self-harm and suicidal thoughts, or that assesses the effectiveness of strategies to reduce the risk of suicide deaths, suicidal behaviours, self-harm and suicidal thoughts, resulting from the COVID-19 pandemic.

Methods
This living systematic review (Figure 1) follows published guidance for such reviews and for how expedited ‘living’ recommendations should be formed where relevant (Akl et al., 2017; Elliott et al., 2017). The review was prospectively registered (PROSPERO ID CRD42020183326; registered on 1 May 2020). An overview of our living review process is provided in Figure 1. A protocol (John et al., 2020a) was published in line with the Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols guideline (Moher et al., 2015). Since publication of our protocol we have amended our methodology to: 1) search additionally the PsyArXiv and SocArXiv open access paper repositories; 2) include modelling studies within the scope of our review (e.g. to predict the likely impact of the pandemic on suicide rates); and 3) update our research questions to include adult self-neglect and parental neglect and fear of losing livelihood.

Eligibility criteria
Study participants may be adults or children of any ethnicities living in any country. Outcomes of interest are:

1. Deaths by suicide
2. Self-harm (intentional self-injury or self-poisoning regardless of motivation and intent) or attempted suicide (including hospital attendance and/or admission for these reasons)
3. Suicidal thoughts/ideation
Studies must address one of the following research questions:

(i) What is the prevalence/incidence?
   - Prevalence/incidence of each outcome during pandemic (including modelling studies)

(ii) What is the comparative prevalence/incidence?
   - Prevalence/incidence of each outcome during pandemic vs not during pandemic

(iii) What are the effects of interventions?
   - Effects of public health measures to combat COVID-19 (including physical distancing, school closures, interventions to address loss of income, interventions to tackle domestic violence) on each outcome
   - Effects of changed and new approaches to clinical management of (perceived) elevated risk of self-harm or suicide risk on each outcome (any type of intervention is relevant)

(iv) What are the effects of other exposures?
   - Impact of media portrayal of each outcome and misinformation attributed to the pandemic on each outcome
   - Impact of bereavement from COVID-19 on each outcome
   - Impact of any COVID-19 related behaviour changes (domestic violence, alcohol, adult self-neglect, parental neglect, cyberbullying, isolation) on each outcome
   - Impact of COVID-19-related workload on crisis lines on each outcome
   - Impact of infection with COVID-19 (self or family member) on each outcome
   - Impact of changes in availability of analgesics, firearms and pesticides on each outcome (method-specific and overall suicide rates)
   - Impact of COVID-19 related socio-economic exposures (changes in fiscal policy; recession/depression: unemployment, debt, fear of losing livelihood, deprivation at the person-, family- or small-area level) on each outcome
   - Impact on health and social care professionals: the stigma of working with COVID-19 patients or the (perceived) risk of infection/being a ‘carrier’, as well as work-related stress on each outcome
   - Impact of changes in/reduced intensity of treatment for patients with mental health conditions, in particular those with severe psychiatric disorders.

Figure 1. Workflow for updating the living systematic review review. The process will be supported using automation technology and at three-monthly intervals the team will update the published version of the review. The latest and previous versions of this figure are available as extended data (John & Schmidt, 2020).
• Impact of any other relevant exposure on our outcomes of interest.

Qualitative research
We include any qualitative research addressing perceptions or experiences around each outcome in relation to the COVID-19 pandemic (e.g. stigma of infection, isolation measures, complicated bereavement, media reporting, experience of delivering or receiving remote methods of self-harm/suicide risk assessment or provision of treatment; experience of seeking help for individuals in suicidal crisis); narratives provided for precipitating factors for each outcome.

No restrictions were placed on the types of study design eligible for inclusion, except for the exclusion of single-person case reports. Pre-prints were re-assessed at the time of publication and most current version included. There was no restriction on language of publication. We will draw on a combination of internet-based translation systems and network of colleagues to translate evidence in a language other than English.

Identification of eligible studies
We searched the following electronic databases: PubMed; Scopus; medRxiv, bioRxiv; the COVID-19 Open Research Dataset (CORD-19) by Semantic Scholar and the Allen Institute for AI, which includes relevant records from Microsoft Academic, Elsevier, arXiv and PMC; and the WHO COVID-19 database. A sample search strategy (for PubMed) appears in Box 1 from 1st Jan 2020 to June 7th 2020. We have developed a workflow that automates daily searches of these databases, and the code supporting this process can be found at https://github.com/mcguilu/COVID_suicide_living. Searches are conducted daily via PubMed and Scopus application programme interface and the bioRxiv and medRxiv RSS feeds. Conversion scripts for the daily updated WHO and the weekly updated CORD-19 corpus are used to collect information from the remaining sources. The software includes a systematic search function based on regular expressions to search results retrieved from the WHO, CORD-19 and preprint repositories (search strategy available in extended data (John & Schmidt, 2020)). Our review is ongoing and we continue to investigate the use of other databases and to capture articles made available prior to peer review and assess eligibility and review internally. We therefore included PsyArXiv and SocArXiv repositories in our search strategy via their own open access platforms as we developed our automated system. For this version of the living review, Psy- and SocArXiv searches were carried out retrospectively on the 12th of June, using a publication date filter for Jan 1st 2020 – June 7th 2020.

A two-stage screening process was undertaken to identify studies meeting the eligibility criteria. First, two authors (either CO or EE) assessed citations from the searches and identified potentially relevant titles and abstracts. Second, either DG, AJ or RW assessed the full texts of potentially eligible studies to identify studies to be included in the review. This process was managed via a custom-built online platform (Shiny web app, supported by a MongoDB database). The platform allowed for data extraction via a built-in form.

Box 1. Search terms for PubMed

Data collection and assessment of risk of bias
One author (DG, AJ or RW) extracted data from each included study using a piloted data extraction form (see extended data (John & Schmidt, 2020)), and the extracted data were checked by one other author (AJ, or EE where AJ extracted data). Disagreements were resolved through discussion, and where this failed, by referral to a third reviewer (KH, NK or PM). Irrespective of study design, data source and outcome measure examined, the following basic data were extracted: citation; study aims and objectives; country/setting; characteristics of participants; methods; outcome measures (related to self-harm / suicidal behaviour and COVID-19); key findings; strengths and limitations; reviewer’s notes. For articles where causal inferences are made - i.e. randomised or non-randomised studies examining the effects of interventions or aetiological epidemiological studies of the effects of exposures – we used a suitable version of the ROBINS-I or ROBINS-E tool to assess risk of bias as appropriate based on the research question and study design (Morgan et al., 2017; Sterne et al., 2016).

Data synthesis
We synthesised studies according to themes based on research questions and study design, using tables and narrative. Results were synthesised separately for studies in the general population, in health and social care staff and other at-risk occupations, and in vulnerable populations (e.g. people of older age or those with underlying conditions that predispose them to becoming severely ill or dying after contracting COVID-19). Where multiple studies addressed the same research questions, we assessed whether meta-analysis is appropriate and would conduct it where suitable, following standard guidance available in the Cochrane Handbook (Deeks et al., 2019). The current document is the first iteration of our review. We have not considered
it appropriate to combine any results identified so far in a meta-analysis.

**Living review method**
Details of the living review method, justification for its use and our transition plan are provided in our protocol (John et al., 2020a). We plan to maintain the review in living mode for at least 12 months, from publication of the protocol (25th June 2020). We will undertake monthly screening and consider full updates at least every three months. We will extend the living mode at 6-monthly intervals if evidence is still being published regularly. We anticipate an end to the living phase of the review at most 24 months after initiation, at which point we plan to publish the cumulated evidence in the form of a standard systematic review. Any decision to update the review more or less frequently will depend on the likely impact of the new evidence on the conclusions of the review. Impactful evidence may be (i) evidence that affects policy and/or (ii) substantial, high-quality research studies (e.g. a randomised trial or population-based observational cohort study). Since we have not as yet identified any new evidence that impacts on the conclusions of this review we next update will include studies up to the 7th of October 2020 after four months.

**Results**
In total, 2070 citations were identified by 7 June 2020 from all electronic searches, after duplicates were removed (Figure 2).

The cumulative numbers of articles over time that were identified by the search and included in the review are shown in Figure 3 and Figure 4.

**Description of included studies**
We included 29 articles in the review, describing 28 independent studies. In total, six studies spanned several countries or were worldwide, including those using online Amazon Mechanical Turk survey samples; six were from the United States; four from China; two from India; one each from Australia, Bangladesh, Canada, Germany, Greece, Pakistan, Spain, France and Switzerland. All articles were based on observational studies: eight were case series with a sample of two or more; 13 were cross sectional surveys (12 independent populations); five were modelling studies; and three were service utilisation studies. Studies are summarised by these study types in Table 1, Table 2, Table 3 and Table 4. Roughly half (n=14) of the articles did not appear to have been peer reviewed. Ten articles were published as research letters to the Editor, four as pre-prints before peer review and in seven others there was a short time (<7 days) between submission and acceptance.

**Study populations**
Two articles shared study populations (Killgore et al., 2020a; Killgore et al., 2020b). Excluding duplicate populations and modelling studies, the total number of unique participants was 33,345. Most studies included both male and female
participants except (Wu et al., 2020b) which was conducted in a population of pregnant women in their third trimester.

Outcomes
Two of the eight case series focused on suicide attempts and six on suicide deaths. Of the 12 independent cross-sectional surveys ten assessed suicidal thoughts of which two also assessed suicide attempts (Ammerman et al., 2020; Bryan et al., 2020), one thoughts of self-harm (Wu et al., 2020b) using a single item from the Edinburgh Postnatal Depression Scale (EPDS), one suicidality (Kaparounaki et al., 2020) using the Risk Assessment Suicidality Scale (RASS). A range of validated questionnaires were used to assess suicidal thoughts. Four used the question 9 single item from PHQ-9 ‘Have you had thoughts that you would be better off dead or of hurting yourself in some way’ with four levels of response ranging from ‘not at all’ to ‘nearly every day’ over the last 2 weeks. One each used: the Beck Depression Inventory-II (with one item where the participant choses...
Table 1. Summary of included case series. The latest and previous versions of this table are available as extended data (John & Schmidt, 2020).

**Conclusions**

Respondents reported a 20.2% increase in ‘overall suicidality’ higher RASS scores than the general population in 2012.

Suicidality RASS suicidality scale (Fountoulakis, 2012)

Lonely individuals (M=0.55±0.88) scored significantly higher than non-lonely (M=0.07±0.36) respondents on the PHQ-9 suicidal ideation item (F1,997=138.13, p<.00001, partial η2=.12). 34.4% of lonely respondents endorsed some level of suicidal ideation compared to 29.9% of non-lonely participants (OR: 1.10, 95% CI: 0.94-1.29, p<.00001).

Authors suggest impact of social distancing on loneliness and suicidal ideation is tangible at a population level. Cross-sectional analysis of the association between COVID-related worries and suicidal thoughts and sleep mediation.

As above.

A logistic regression, which controlled for sociodemographic effects of age, gender, education, and race, demonstrated that dysfunctional coronavirus anxiety was associated with suicidal ideation (odds ratio 1.24, 95% CI: 1.13–1.37).

Comment/ Limitations

Definition of ‘suicidality’ not given. Little methodological information. Letter to editor, probably not peer reviewed.

No detailed discussion of sampling frame. Authors suggest impact of social distancing on loneliness and suicidal ideation is tangible at a population level. Letter to editor, probably not peer reviewed. The comparison population is derived from the literature and it is unclear if it includes all ages rather than people of the same age as the students (mean age 22 yrs, 68% females).

one statement from among a group of four statements that best describes how they have been feeling during the past few days, ranging from ‘I don’t have thoughts of killing myself’ to ‘I would kill myself if I had the chance’; the WHO Self Reporting Questionnaire (with one item of 20 asking ‘Has the thought of ending your life been on your mind?’; response yes/no in the last 30 days); one used the question how many times over the last two weeks have you thought ‘I wished I was already dead so I did not have to deal with the coronavirus’ on a five point scale; and in two little detail was given regarding this outcome assessment.

Two studies used the Self-injurious Thoughts and Behaviours Interview (SITBI) to assess for presence (yes/no) of active suicidal thoughts (i.e., ‘Have you had thoughts of killing yourself?’) in the past month (Ammerman et al., 2020) and the other in the past month, year or over a year ago (Bryan et al., 2020). They also included the item for suicide attempts. Ammerman et al. (2020) used one adapted item from the SITBI ‘In the past month, have you attempted to kill yourself?’ (yes/no) and Bryan et al. (2020) ‘Have you ever made an actual attempt to kill yourself in which you had at least some intent to die?’ (yes/no) within the past month, year or more than a year ago.

Summary of studies’ findings: Case series
We identified eight case series reports of suicide attempts and suicide deaths (Table 1). Five of these used news reports as their data source (Bhuiyan et al., 2020; Dsouza et al., 2020; Griffiths & Mamun, 2020; Mamun & Ullah, 2020; Thakur & Jain, 2020). Many reasons for COVID-19 related suicide or suicide attempts were suggested and usually this information was derived from a journalist’s report of the death. Contributory factors reported included fear of contracting the disease or of passing it on to others, reactive psychoses, financial or economic issues, loneliness and isolation due to quarantine, stress among health professionals, the uncertainty around when the pandemic would end, an inability for migrants to return home, frustration and the stigma of a (possibly perceived) positive result, which resulted in harassment or victimisation by others in the community. The largest case series (Dsouza et al., 2020) (n=72 suicide deaths) reported that the most commonly occurring antecedents to suicide were fear of infection (n=21) and financial crisis (n=19). One case series (Griffiths & Mamun, 2020), based on news reports, included suicide pacts by 6 couples (including one murder suicide and one double suicide attempt) from Bangladesh, India, Malaysia and the USA.

Summary of studies’ findings: Cross-sectional surveys
There were 13 articles describing cross-sectional surveys, reporting 12 independent studies (Table 2). Seven articles (6 independent studies) reported cross-sectional surveys in the general population. One study (Killgore et al., 2020a; Killgore et al., 2020b) was a nationally representative sample of English speaking participants aged 18-35 years from 50 US states; however, no details were given regarding how the participants were sampled. Bryan et al. (2020) used a panel quota sampling methodology and weighted their sample to match the USA general population by age, sex and ethnicity. Three studies used convenience sampling through Amazon Mechanical Turk crowd-sourcing (Ammerman et al., 2020; Lee, 2020; Lee et al., 2020), which pays survey responders a small fee for participation and one (Plomecka et al., 2020) used online recruitment.

Participants were COVID-19 patients in three studies (Hao et al., 2020; Wu et al., 2020a; Zhao et al., 2020) and surveys were targeted at specific populations in a further three: pregnant women (Wu et al., 2020b), neurosurgeons (Sharif et al., 2020) and university students (Kaparounaki et al., 2020). The study by Wu et al. (2020b) was the only survey to report pre-pandemic/pre-illness data for comparison, although Killgore et al. (2020a) compared their findings to previous work (Morahan-Martin & Schumacher, 2003) and a number of studies compared their findings to estimates that were reported from earlier published studies.

Higher levels of suicidal/self-harm thoughts were reported in individuals with: anxiety relating to COVID-19 (Lee, 2020); worry relating to COVID-19 mediated by insomnia (Killgore et al., 2020b); with loneliness (Killgore et al., 2020a); worsening of pre-existing mental illness during COVID-19 (Hao et al., 2020; Plomecka et al., 2020); and in students (Kaparounaki et al., 2020); people recovering from COVID-19 infection (Hao et al., 2020); as well as women who were in their third trimester of pregnancy during the pandemic, compared with measures taken amongst women at the same stage of pregnancy before the pandemic (Wu et al., 2020b). As these are cross-sectional studies the direction of association is not possible to determine and only one study used pre-pandemic measures recorded in the same population in a similar way (Wu et al., 2020b).

One study carried out in the USA exploited the natural experiment provided by states imposing physical distancing measures on different dates (Bryan et al., 2020). This study found no evidence of an increased risk of suicidal thoughts or attempts amongst those living in states with either stay-at-home orders or restrictions on large gatherings in place compared with states without these measures.

Summary of studies’ findings: Modelling studies
We identified five studies (Table 3) that have used modelling approaches to forecast the potential impact of the pandemic on future suicide rates (Bhata, 2020; Kawohl & Nordt, 2020; McIntyre & Lee, 2020a; McIntyre & Lee, 2020b; Moser et al., 2020). Each was based on different assumptions, but models largely focused on the well-characterised impact on suicide rates of rises in unemployment (Chang et al., 2013; Stuckler et al., 2009). Unemployment rates are predicted to rise as a result of a post-pandemic recession, due to measures to control the spread of the virus on the wider economy and loss of work as many businesses have been forced to shut down.

Only one study modelled the effects of physical distancing measures on suicide rates (Moser et al., 2020); it did this by using suicide rates in prisoners in group or single cells as a model for lock-down in a group or in isolation. The prison population is exposed to multiple other risk factors for suicide
(e.g., increased prevalence of mental illness, substance misuse and low socioeconomic position) (Humber et al., 2011; Rivlin et al., 2010), and this, coupled with the distinct differences between prison incarceration and the adoption of home quarantine procedures during the pandemic, this model is likely to over-estimate the potential impact of physical distancing measures on suicide.

The models suggest between a 1% rise (globally) (Kawohl & Nordt, 2020) and a 145% rise (in Switzerland) (Moser et al., 2020) in suicide deaths.

**Summary of studies' findings: Service utilisation studies**

We identified three service utilisation studies (Pignon et al., 2020; Smalley et al., 2020; Titov et al., 2020) (Table 4). Smalley et al. (2020) reported a fall in ED visits for suicidal thoughts in Midwest USA, as well as a fall in the proportion of total visits that were for suicidal thoughts. In contrast Titov et al. (2020) found evidence of increased contact volume to a national digital mental health service in Australia. However, amongst contacts, while there was evidence of increased anxiety and levels of concerns about COVID-19, which increased with age, there was no evidence that the percentage of contacts with suicidal thoughts/plans increased. Pignon et al., 2020 reported that emergency psychiatric consultations for suicide attempts more than halved in a region of Paris in the first month of lockdown, compared to the same period in 2019.

**Discussion**

In total, 28 independent studies (29 articles) were included in this review covering a total of 33,345 studied individuals from around the world with a mix of low, middle and high income countries. Almost half of the articles were pre-prints published before peer review, or research letters that may not have been peer-reviewed. The majority of studies were case series or cross-sectional surveys, almost all based on non-representative convenience samples. Only one study reported on the change in incidence of suicide or suicidal behaviour before versus after the onset of the pandemic (Pignon et al., 2020); this analysis was based on emergency psychiatric consultations for suicide attempt – and reported a decline, although levels of consultation could have been influenced by fears about using services or ideas of not burdening the health service rather than changes in incidence. A further study from China reported heightened levels of self-harm thoughts in pregnant women surveyed in the period after the onset of the pandemic, compared with levels reported amongst women surveyed at the same stage of pregnancy just before the pandemic (Wu et al., 2020b). No studies reported potentially harmful effects of lockdown/physical distancing measures in relation to our outcomes, although one study comparing the prevalence of suicidal thoughts and attempts in people living in USA states with varying timing and stringency of state-specific lockdowns found no evidence for such an ecological association (Bryan et al., 2020). Modelling studies that aimed to predict the impact of the pandemic on national or global suicide rates produced widely differing estimates of the likely impact and most focused on predictions based on previous studies of the impact of changes in unemployment levels on suicide. Three studies investigated service use patterns – one found a decline in ED visits for suicidal thoughts, one a decline in psychiatric emergency consultation for suicide attempt and the other reported an increase in contacts to a mental health digital platform but no changes in contacts for suicidal thoughts.

We identified eight case series reports of suicide attempts and suicide deaths, five based on news stories in India, Bangladesh and Pakistan. Given the relatively low quality of case series in the hierarchy of evidence, often reflecting small numbers and selection bias, but more importantly the lack of comparator data, drawing any reliable inferences from these studies is challenging. Furthermore, news reports report a non-representative sample of suicide deaths and often derive their information from bystanders and witnesses who are unlikely to know the full circumstances of the death (Khan et al., 2009). Nevertheless, these studies highlight circumstances surrounding apparently COVID-19-related suicides and flag the potential importance of factors such as economic difficulties, fear of the disease, and social isolation. Indeed in parts of the world without reliable suicide incidence data they may be the only source of information (Khan & Hyde, 2006).

The 12 cross-sectional studies investigated a range of issues. Findings indicated worries about COVID-19 and recent COVID-19 infection were associated with suicidal thoughts (Hao et al., 2020; Killgore et al., 2020a; Killgore et al., 2020b; Lee, 2020; Lee et al., 2020; Zhao et al., 2020) and, amongst pregnant women surveyed during the pandemic, thoughts of self-harm were higher than amongst those surveyed pre-pandemic. The one study comparing suicidal thoughts and behaviours amongst people living in areas with versus without physical distancing measures found no adverse association (Bryan et al., 2020). Surprisingly, a survey by Ammerman et al. (2020) from the USA indicated that social distancing was associated with reduced instances of suicidal thoughts early in the period of lockdown. Only one survey suggested it was nationally representative but lacked sampling details (Killgore et al., 2020a). Non-probabilistic sampling lacks a sound theoretical basis for statistical inference (Neyman, 1934). Consequently, basic descriptive analyses and explorations of potential associations are appropriate but measures of uncertainty (i.e., confidence intervals around estimates of prevalence) are generally not valid. One study (Bryan et al., 2020) used panel quota sampling, but these sorts of adjustments for age, sex and ethnicity may miss other elements of bias and cannot account for groups not included at all, particularly if the response rate is unknown (Pierce et al., 2020). Four studies used convenience sampling which tend to attract volunteers who have access to the internet, are already engaged in research and have an interest in the topic. Hence responses may be unrepresentative of the general population, and associations observed among these healthy volunteers may not reflect associations that would be observed in others. Similarly, when assessing suicidal thoughts and behaviours, those in most distress or with co-existing mental illness, as well as older people, are less likely to participate in these sorts of surveys. There is no way to assess non-response bias in a convenience sample as might be possible in a probability-sampled survey (Pierce et al., 2020).
There was a large range in modelling estimates of the effect of the pandemic on suicide rates, varying between a 1% and a 145% rise. These differences between model estimates were partly due to differences in modelling assumptions, which are associated with considerable uncertainty. Given the methodological limitations, the uncertainty of assumptions about how the economies of individual countries will be affected, as well as international differences in financial supports given to businesses and people out of work, these predictive exercises can at best only provide a guide as to where action should be directed.

**Strengths and Limitations**

To date, there is little literature exploring COVID-19 and suicide deaths, suicidal behaviours, self-harm and suicidal thoughts and most of the published evidence that we identified had important limitations. Importantly, much of the literature is not yet peer reviewed so the quality of reported studies may change. There were eight research letters, five pre-prints and for many others very short timeframes between submission and acceptance. All included studies were observational in design and prone to multiple sources of bias (eg, recall bias, selection bias, confounding). No conclusions can be drawn regarding causality and temporality from cross sectional studies. However, such study designs may be appropriate in current circumstances where timeliness of studies to inform policy and practice are important. However many were carried out too quickly and too early (one to two weeks post lockdown) in the outbreak to make meaningful contributions to the evidence base. The lack of baseline data in the majority of surveys included in the review and adjustments made to standardised measures to assess suicidal behaviours as well as the range of measures and timing asked made assessment of findings problematic.

We did not include Google Trends studies (Jacobson et al., 2020; Knipe et al., 2020; Rana, 2020; Sinyor et al., 2020) since search data constitute a proxy measure but findings are largely mixed. We also excluded grey literature (Fancourt & Steptoe, 2020).

**Implications**

A marked improvement in the quality of design, methods, and reporting in future studies is needed. There is thus far no clear evidence of an increase in suicidal behaviour or self-harm associated with the pandemic nor with the measures taken to curb the spread of COVID-19. The current iteration of out living review highlights the methodological issues of early evidence from around the world that assesses the impact of the COVID-19 pandemic on suicide deaths, suicidal behaviours, self-harm and suicidal thoughts, or that assesses the effectiveness of strategies to reduce the risk of suicide deaths, suicidal behaviours, self-harm and suicidal thoughts, resulting from the COVID-19 pandemic. However, suicide data are challenging to collect in real time and the economic effects are evolving. Our living review will provide a regular synthesis of the most up-to-date research evidence to guide public health and clinical policy to mitigate the impact of COVID-19 on suicide.

**Data availability**

**Underlying data**

This project contains the following underlying data:

- Screening_snapshot.csv (Screening progress for literature published before June 7th)

**Extended data**

This project contains the following extended data:

- LSR update tables and figures.docx (Tables and figures from this publication)
- PRISMA.doc

Data regarding the Protocol are available via our Harvard Dataverse repository for the protocol

That project contains the following extended data:

- Search.docx (additional information about the searches, including full search strategies)
- Data extraction sheet/ study report
- Figure 1
- Prisma.pdf (the PRISMA-P statement)
- Prospero registration

**Reporting guidelines**

Data are available under the terms of the Creative Commons Attribution 4.0 International license (CC-BY 4.0).

**Software availability**

The development version of the software for automated searching is available from Github: https://github.com/mcguinlu/COVID_suicide_living.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage
